MORE ON ZEROS AND APPROXIMATION
OF THE ISING PARTITION FUNCTION

ALEXANDER BARVINOK AND NICHOLAS BARVINOK

May 27, 2020

Abstract. We consider the problem of computing the partition function
\[ \sum_x e^{f(x)}, \]
where \( f : \{-1, 1\}^n \to \mathbb{R} \) is a quadratic or cubic polynomial on the Boolean cube \( \{-1, 1\}^n \). In the case of a quadratic polynomial \( f \), we show that the partition function can be approximated within relative error \( 0 < \epsilon < 1 \) in quasi-polynomial \( n^{O(\ln n - \ln \epsilon)} \) time if the Lipschitz constant of the non-linear part of \( f \) with respect to the \( \ell^1 \) metric on the Boolean cube does not exceed \( 1 - \delta \), for any \( \delta > 0 \), fixed in advance. For a cubic polynomial \( f \), we get the same result under a somewhat stronger condition. We apply the method of polynomial interpolation, for which we prove that \( \sum_x e^{\tilde{f}(x)} \neq 0 \) for complex-valued polynomials \( \tilde{f} \) in a neighborhood of a real-valued \( f \) satisfying the above mentioned conditions. The bounds are asymptotically optimal. Results on the zero-free region are interpreted as the absence of a phase transition in the Lee - Yang sense in the corresponding Ising model. The novel feature of the bounds is that they control the total interaction of each vertex but not every single interaction of sets of vertices.

1. Introduction and main results

The Ising model is one of the oldest, most famous and most studied models in statistical physics, see [FV18] for a thorough introduction, description, results and references. In this paper, we look at the computational complexity and complex zeros of the partition function in the Ising model. This is a classical and also currently very active area of research, see [B+19], [G+19], [J+19], [L+12], [L+16], [L+19a], [L+19b], [PR20], [S+14] and [Z+11] for some recent results.

Formally, the partition function we work with is described as follows. Let \( \{-1, 1\}^n \) be the \( n \)-dimensional Boolean cube of all \( n \)-vectors \( x = (\xi_1, \ldots, \xi_n) \), where
\( \xi_i = \pm 1 \) for \( i = 1, \ldots, n \) and let \( f : \{-1,1\}^n \rightarrow \mathbb{C} \) be a function. We define the partition function as
\[
S(f) = \sum_{x \in \{-1,1\}^n} e^{f(x)}.
\]

In this paper, we consider the cases of a quadratic
\[
f(x) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^n b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n)
\]
or cubic
\[
f(x) = \sum_{1 \leq i < j < k \leq n} c_{ijk} \xi_i \xi_j \xi_k + \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^n b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n)
\]

polynomial \( f \) and we are interested to compute (approximate) \( S(f) \) efficiently.

The case of a quadratic polynomial \( f \) is the best studied. Often, there is an underlying \( G \) with vertices numbered \( 1, \ldots, n \) and the property that \( a_{ij} \neq 0 \) if and only if \( i \) and \( j \) span an edge of \( G \). In this case, the variable \( \xi_i = \pm 1 \) is interpreted as the spin of a vertex \( i \) and \(-f(x)\) as the energy of the configuration \( x = (\xi_1, \ldots, \xi_n) \).

The coefficients \( a_{ij} \) describe the interactions of vertices \( i \) and \( j \): the interaction is ferromagnetic if \( a_{ij} > 0 \) and antiferromagnetic if \( a_{ij} < 0 \). The coefficients \( b_i \) describe the external field, see [FV18] for a thorough discussion.

Via the method of polynomial interpolation [Ba16], we relate the computational complexity to the absence of complex zeros of \( S(f) \) in the vicinity of real coefficients \( a_{ij} \) and \( b_i \) and \( c_{ijk} \). For quadratic polynomials, we prove the following main result.

(1.1) Theorem. Let
\[
f(x) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^n b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n).
\]

Suppose that for some \( 0 < \delta < 1 \), we have
\[
\sum_{j: j \neq i} |\Re a_{ij}| \leq 1 - \delta, \quad \sum_{j: j \neq i} |\Im a_{ij}| \leq \frac{\delta^2}{10} \quad \text{and} \quad |\Im b_i| \leq \frac{\delta^2}{10}
\]

for \( i = 1, \ldots, n \). Then
\[
\sum_{x \in \{-1,1\}^n} e^{f(x)} \neq 0.
\]

A remark regarding notation: we treat indices \( i, j \) in \( a_{ij} \) as an unordered pair, so \( a_{ij} \) is the coefficient of the monomial \( \xi_i \xi_j \) in the quadratic polynomial \( f \) and the sum \( \sum_{j: j \neq i} \) accounts for all coefficients \( a_{ij} \) of the monomials containing \( \xi_i \). For a
complex number $z = x + y\sqrt{-1}$, we denote by $\Re z = x$ and $\Im z = y$ the real and imaginary parts of $z$ respectively.

From Theorem 1.1, the by now standard polynomial interpolation argument, (see [Ba16], [G+19], [L+19a], [L+19b], [PR17]), produces an algorithm for approximating the partition function $S(f)$ when the coefficients $a_{ij}$ and $b_i$ are real and satisfy the condition

$$\sum_{j: j \neq i} |a_{ij}| \leq 1 - \delta \quad \text{for} \quad i = 1, \ldots, n,$$

where $0 < \delta < 1$ is fixed in advance. As there is no restriction on $b_i$, the sum $S(f)$ can be exponentially large in $|b_i|$. To avoid dealing with exponentially large numbers, we assume that we are provided with numbers $e^{b_i}$ for $i = 1, \ldots, n$. Then the complexity of the algorithm is quasi-polynomial: we approximate $S(f)$ within relative error $0 < \epsilon < 1$ in $n^{O(\ln n - \ln \epsilon)}$ time.

We describe the algorithm in Section 4 and prove Theorem 1.1 in Section 2. Next, we relate Theorem 1.1 to what is known about the partition function in the Ising model.

(1.2) The bounds for the zero-free region are asymptotically optimal. Let $G$ be a graph with vertices $1, \ldots, n$. For a real number $a$, let us choose

$$(1.2.1) \quad a_{ij} = \begin{cases} a & \text{if } \{i, j\} \text{ is an edge of } G \\ 0 & \text{otherwise} \end{cases}$$

and let us choose $b_i = b$ for some $b \in \mathbb{C}$ for all $i = 1, \ldots, n$. Let us fix some positive integer $\Delta \geq 3$ and choose either

$$(\text{all interactions are ferromagnetic}) \quad a = \frac{1}{2} \ln \frac{\Delta}{\Delta - 2}$$

or

$$(\text{all interactions are antiferromagnetic}) \quad a = \frac{1}{2} \ln \frac{\Delta - 2}{\Delta}$$

We consider the partition function $S(f)$ as a function of a complex parameter $b$. It is known that for a fixed $\Delta$, as $n$ grows and $G$ ranges over all graphs with the largest degree $\Delta$ of a vertex, the zeros of the univariate function $b \mapsto S(f)$ with either choice of $a$ can get arbitrarily close to $b = 0$, see [BM97], [BG01], [PR20], [B+19]. We have

$$\sum_{j: j \neq i} |\Re a_{ij}| \leq \frac{\Delta}{2} \ln \frac{\Delta}{\Delta - 2}.$$ 

The right hand side approaches 1 as $\Delta \to \infty$, which shows that “1” in the “$1 - \delta$” bound of Theorem 1.1 cannot be replaced by a larger number.
(1.3) The bounds for approximation are asymptotically optimal in the antiferromagnetic case. As in Section 1.2, let $G$ be a graph of the largest degree $\Delta \geq 3$, let us choose all $b_i = 0$ for all $i = 1, \ldots, n$ and let us define $a_{ij}$ by (1.2.1). Suppose that

$$ a < \frac{1}{2} \ln \frac{\Delta - 2}{\Delta}. $$

It is shown in [SS14] and also in [G+16] that the problem of approximating $S(f)$ is NP-hard under randomized reduction. Hence unless the computational complexity hierarchy collapses, we cannot approximate $S(f)$ in quasi-polynomial time in the class of problems where all $b_i = 0$ and

$$ \sum_{j: j \neq i} |a_{ij}| \leq 1 + \delta \quad \text{for} \quad i = 1, \ldots, n $$

for an arbitrarily small $\delta > 0$, fixed in advance.

(1.4) The ferromagnetic case is special. Suppose that $a_{ij} \geq 0$ for all $i, j$ and that $b_i = b$ for $i = 1, \ldots, n$ and some complex parameter $b$. Lee and Yang [LY52] showed that the zeros of the univariate function $b \mapsto S(f)$ lie on the line $\Re b = 0$. If the $b_i$ are allowed to vary, then $S(f) \neq 0$ as long as $\Re b_i > 0$ for $i = 1, \ldots, n$. The ferromagnetic case is also special from the complexity point of view: Jerrum and Sinclair [JS93] constructed a randomized polynomial time algorithm approximating $S(f)$ when $b_i = b$ for some real $b$ and $i = 1, \ldots, n$. Deterministic approximation algorithms of quasi-polynomial (genuinely polynomial, if the largest degree $\Delta$ of the underlying graph $G$ is fixed in advance) complexity, are constructed in [L+19b], assuming that $\Re b_i \geq \delta > 0$ for some constant $\delta > 0$, fixed in advance, and $i = 1, \ldots, n$, see also Section 7.4 of [Ba16]. The complexity status of the approximation problem in the ferromagnetic case of $a_{ij} \geq 0$ and $b_i = 0$ by a deterministic algorithm appears to be not known.

(1.5) The bounds for phase transition are asymptotically optimal.

Theorem 1.1 can be interpreted as saying that there is no phase transition in the Lee - Yang sense [YL52] provided the parameters $a_{ij}$ and $b_i$ are real and satisfy (1.1.1) for some $0 < \delta < 1$, fixed in advance. There is a related, though not identical, concept of phase transition, based on the disappearance of correlation decay, see [FV18]. If we choose $b_i = 0$ for all $i$ and define $a_{ij}$ as in (1.2.1), then the correlation decay occurs precisely in the interval

$$ \frac{1}{2} \ln \frac{\Delta - 2}{\Delta} < a < \frac{1}{2} \ln \frac{\Delta}{\Delta - 2}, $$

where $\Delta \geq 3$ is the largest degree of a vertex of $G$, see [Z+11], [S+14], and [L+19a]. In view of (1.2.2), the bound (1.1.1) is asymptotically optimal as $\Delta \rightarrow \infty$.

We extend the bounds of Theorem 1.1 to cubic polynomials on the Boolean cube $\{-1, 1\}^n$. 4
Theorem. Let
\[ f(x) = \sum_{1 \leq i < j < k \leq n} c_{ijk} \xi_i \xi_j \xi_k + \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^{n} b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n). \]

Suppose that for some \(0 < \delta < 1/2\), we have
\[ \sum_{j,k: j,k \neq i} |\Re c_{ijk}| + \sum_{j: j \neq i} |\Re a_{ij}| \leq 1 - \delta, \quad \sum_{j,k: j,k \neq i} |\Im c_{ijk}| + \sum_{j: j \neq i} |\Im a_{ij}| \leq \frac{\delta^2}{10} \]
and \( |\Im b_i| \leq \frac{\delta^2}{10} \)
for \(i = 1, \ldots, n\). Then
\[ \sum_{x \in \{-1,1\}^n} e^{f(x)} \neq 0. \]

Similarly to the quadratic case, we treat indices \(i, j, k\) in \(c_{ijk}\) as unordered triples of distinct numbers, so that \(c_{ijk}\) is the coefficient of the monomial \(\xi_i \xi_j \xi_k\) in the cubic polynomial \(f\) and the sum \(\sum_{j,k: j,k \neq i}\) accounts for all coefficients \(c_{ijk}\) of the monomials containing \(\xi_i\). As in the case of quadratic polynomials, we obtain an algorithm of quasi-polynomial \(n^{O(\ln n - \ln \epsilon)}\) complexity approximating
\[ S(f) = \sum_{x \in \{-1,1\}^n} e^{f(x)} \]
within relative error \(0 < \epsilon < 1\), provided the coefficients \(c_{ijk}\), \(a_{ij}\) and \(b_i\) are real and satisfy
\[ (1.6.1) \sum_{j,k: j,k \neq i} |c_{ijk}| + \sum_{j: j \neq i} |a_{ij}| \leq 1 - \delta \quad \text{for} \quad i = 1, \ldots, n. \]

The bounds here are asymptotically optimal, for the trivial reason that they are asymptotically optimal in the quadratic case when \(c_{ijk} = 0\) for all \(1 \leq i < j < k \leq n\).

Although Theorem 1.1 is a particular case of Theorem 1.6, we first prove Theorem 1.1 in Section 2 and then describe in Section 3 how to adjust the proof of Theorem 1.1 to obtain Theorem 1.6. We think that this way it is easier to see the idea of the proofs. In Section 3, we also mention where our method falls short extending the bounds to polynomials of degree 4 and higher. We don’t discuss the corresponding extension of the approximation algorithm of Section 4 from quadratic to cubic polynomials, as it is quite straightforward.
What’s new. In the case of a quadratic polynomial, the bound (1.1.1) states that the Lipschitz constant of the non-linear part of \( f : \{-1,1\}^n \rightarrow \mathbb{R} \) does not exceed \( 1 - \delta \) with respect to the \( \ell^1 \) metric (which is twice the Hamming metric) on the Boolean cube \( \{-1,1\}^n \). This is where our approach to approximation differs from those of [G+19], [L+12], [L+19a], [L+19b], [S+14] and [Z+11], which require a uniform bound on the strength of individual interactions \( a_{ij} \), such as

\[
\text{(1.7.1)} \quad \max_{i,j} |a_{ij}| \leq \frac{1}{2} \ln \frac{\Delta}{\Delta - 2}
\]

where \( \Delta \) is the largest degree of the underlying graph. As we remarked above, our results are asymptotically optimal, when \( \Delta \rightarrow \infty \). Generally, the condition (1.1.1) appears to be more robust than (1.7.1), as (1.1.1) is independent on the degree \( \Delta \) and allows individual coefficients \( a_{ij} \) to be relatively large, as long as the sum for all interactions of any given vertex remains appropriately bounded. Of course, for any particular \( \Delta \), the conditions (1.1.1) and (1.7.1) are in general position, as it is easy to construct examples where one holds and the other is violated.

A novelty of our approach with respect to locating zero-free regions of \( S(f) \), compared to those of [G+19], [L+19a], [B+19] and [PR20], is that we allow all parameters \( a_{ij} \) and \( b_i \) to vary: this concerns both Lee - Yang zeros [LY52], [B+19], [PR20] of \( S(f) \) as a function of \( b_i \) with fixed \( a_{ij} \) and Fisher zeros [L+19a] of \( S(f) \) as a function of \( a_{ij} \) with \( b_i \) fixed. It appears that Theorem 1.1 is the first result establishing an asymptotically optimal zero-free region when the interactions \( a_{ij} \) are allowed to differ for different pairs \( \{i,j\} \) and even to be of different signs, so that we have a mixture of ferromagnetic and antiferromagnetic interactions.

There is much less known in the case of cubic and higher degree polynomials on the Boolean cube, see though [L+16] and [L+19b]. In particular, Theorem 1.6 might be the only result that provides asymptotically optimal bounds for cubic polynomials, though the optimality follows by a trivial reduction to the quadratic case. We note that in contrast to (1.1.1), the left hand side of (1.6.1) is not the Lipschitz constant of the non-linear part of \( f \) but an upper bound on that Lipschitz constant.

For polynomials \( f \) of degree \( d \geq 4 \) on the Boolean cube, some, apparently non-optimal, estimates can be found in [Ba17]. Roughly, estimates of [Ba17] require the Lipschitz constant of \( f \) to be \( O\left(1/\sqrt{d}\right)\). It would be interesting to find out if one can get a bound uniform on \( d \).

2. Proof of Theorem 1.1

Definitions and notation. We consider the Boolean cube \( \{-1,1\}^n \) of vectors \( x = (\xi_1, \ldots, \xi_n) \), where \( \xi_i = \pm 1 \) for \( i = 1, \ldots, n \). Let us choose a set \( I \subset \{1, \ldots, n\} \) and numbers \( \sigma_i \in \{-1, 1\} \) for \( i \in I \). The set

\[
F = \{ x \in \{-1,1\}^n : \xi_i = \sigma_i \text{ for } i \in I \}
\]
is called a face of \(\{-1,1\}^n\). Any index \(i \in \{1, \ldots, n\} \setminus I\) is called a free index of the face \(F\) and the number \(n - |I|\) of free indices is called the dimension of \(F\) and denoted \(\text{dim}\ F\). Indexes \(i \in I\) are called fixed. For example, if \(I = \emptyset\) then the face is the whole cube \(\{-1,1\}^n\) and if \(I = \{1, \ldots, n\}\) then the face consists of a single point. Generally, a face of dimension \(k\) consists of \(2^k\) points.

Let \(g : \{-1,1\}^n \to \mathbb{C}\) be a function and let \(F \subset \{-1,1\}^n\) be a face. We define the partial sum of \(g\) on \(F\) by
\[
S(g|F) = \sum_{x \in F} g(x).
\]
We will use the following straightforward identity. Let \(F\) be a face of \(\{-1,1\}^n\) of dimension at least 1. Let \(i\) be a free index of \(F\) and let \(F^+ \subset F\) and \(F^- \subset F\) be the faces obtained by fixing the \(i\)-th coordinate \(\xi_i\) of vectors \(x \in F\) to 1 and \(-1\) respectively. Hence \(F^+ \cup F^- = F\), \(F^+ \cap F^- = \emptyset\) and
\[
(2.1.1) \quad S(g|F) = S(g|F^+) + S(g|F^-).
\]
Let us fix a real number \(0 < \delta < 1\) and a vector \(b = (b_1, \ldots, b_n)\) such that \(|\Im b_i| \leq \delta^2/10\) for \(i = 1, \ldots, n\). We denote by \(U(b; \delta)\) the set of all polynomials \(f : \{-1,1\}^n \to \mathbb{C}\),
\[
f(\xi_1, \ldots, \xi_n) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^n b_i \xi_i,
\]
where
\[
\sum_{j=1}^n |\Re a_{ij}| \leq 1 - \delta \quad \text{and} \quad \sum_{j=1}^n |\Im a_{ij}| \leq \frac{\delta^2}{10} \quad \text{for} \quad i = 1, \ldots, n.
\]
We can view \(U(b; \delta)\) as a convex subset of \(\mathbb{C}^n\) with a non-empty interior. In particular, for any \(f_1, f_2 \in U(b; \delta)\) and any \(0 \leq \alpha \leq 1\), we have \(f \in U(b; \delta)\) for \(f = \alpha f_1 + (1 - \alpha) f_2\).

In what follows, we view non-zero complex numbers \(z \in \mathbb{C} \setminus \{0\}\) as vectors in the plane \(\mathbb{R}^2 = \mathbb{C}\) and measure angles between them.

We start with a simple geometric lemma.

**Lemma.** Let \(w_+, w_- \in \mathbb{C} \setminus \{0\}\) be non-zero numbers such that the angle between \(w_+\) and \(w_-\) does not exceed some \(0 \leq \theta < \pi\) and let \(w = w_+ + w_-\).

1. We have \(w \neq 0\) and, moreover,
\[
\frac{|w_+| + |w_-|}{|w|} \leq \frac{1}{\cos(\theta/2)}.
\]
2. We have
\[
|\Im \frac{w_+ - w_-}{w}| \leq \tan \frac{\theta}{2}.
\]
Proof. Let \( v_+, v_- \) and \( v \) be the orthogonal projections of \( w_+, w_- \) and \( w \) respectively onto the bisector of the angle between \( w_+ \) and \( w_- \). Then

\[
|w| \geq |v| = |v_+ + v_-| = |v_+| + |v_-| \geq \cos(\theta/2)|w_+| + \cos(\theta/2)|w_-|
\]

and the proof of Part 1 follows.

To prove Part 2, let \( u_+ = w_+/w \) and \( u_- = w_-/w \). Then

\[
|u_+ + u_-| = 1
\]

is real and the angle between \( u_+ \) and \( u_- \) does not exceed \( \theta \). Let

\[
\alpha = \arg u_+ \quad \text{and} \quad \beta = -\arg u_-.
\]

Without loss of generality, we may assume that \( 0 < \alpha, \beta < \pi/2 \) and hence \( \alpha + \beta \leq \theta \). Let

\[
c = |u_+| + |u_-| \leq \frac{1}{\cos(\theta/2)}
\]

by Part 1. Since \( \Im(u_+ + u_-) = 0 \), we have

\[
(sin \alpha)|u_+| = (sin \beta)|u_-|
\]

and hence

\[
|u_+| = \frac{c \sin \beta}{\sin \alpha + \sin \beta} \quad \text{and} \quad |u_-| = \frac{c \sin \alpha}{\sin \alpha + \sin \beta}.
\]

We have

\[
|\Im(u_+ - u_-)| = |\Im u_+| + |\Im u_-| = (\sin \alpha)|u_+| + (\sin \beta)|u_-| = \frac{2c(\sin \alpha)(\sin \beta)}{\sin \alpha + \sin \beta}
\]

Since the function \( x \mapsto 1/\sin(x) \) is convex on the interval \( 0 < x < \pi/2 \), the minimum value of

\[
\frac{\sin \alpha + \sin \beta}{(\sin \alpha)(\sin \beta)} = \frac{1}{\sin \alpha} + \frac{1}{\sin \beta}
\]

subject to the constraints \( 0 < \alpha, \beta < \pi/2 \) and \( \alpha + \beta \leq \theta \) is attained at \( \alpha = \beta = \theta/2 \). Consequently,

\[
|\Im(u_+ - u_-)| \leq \frac{2c \sin^2(\theta/2)}{2 \sin(\theta/2)} = c \sin(\theta/2) \leq \tan \frac{\theta}{2},
\]

which proves Part 2. \( \square \)

Part 1 can be extended to the sum of more than two vectors with pairwise angles not exceeding \( \theta \), for which one should require \( \theta < 2\pi/3 \), see Lemma 3.6.3 in [Ba16].
Lemma. Let $F \subset \{-1, 1\}^n$ be a face of $\{-1, 1\}^n$. Suppose that for all $f \in U(b, \delta)$ we have $S\left( e^f | F \right) \neq 0$ and, moreover, the following condition is satisfied: if $i$ is a free index of $F$ and $F^+ \subset F$ and $F^- \subset F$ are the faces obtained by setting the $i$-th coordinate $\xi_i = 1$ and $\xi_i = -1$ respectively, then the angle between the numbers $S\left( e^f | F^+ \right) \neq 0$ and $S\left( e^f | F^- \right) \neq 0$ does not exceed $\theta$ for some $0 \leq \theta < \pi$.

Since $S\left( e^f | F \right) \neq 0$ for all $f \in U(b, \delta)$, $f(\xi_1, \ldots, \xi_n) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^n b_i \xi_i$, and the set $U(b, \delta)$ is simply connected, we can choose a branch of the function $f \mapsto -\to \ln S\left( e^f | F \right)$ for $f \in U(b, \delta)$.

Let us fix two indices $1 \leq p < q \leq n$, at most one of which is free for $F$. Then

$$\left| \frac{\partial}{\partial a_{pq}} \ln S\left( e^f | F \right) \right| \leq \frac{1}{\cos(\theta/2)}$$
and

$$\left| \Im \frac{\partial}{\partial a_{pq}} \ln S\left( e^f | F \right) \right| \leq \frac{\tan \theta}{2}$$

for all $f \in U(b, \delta)$.

Proof. Differentiating, we get

$$\frac{\partial}{\partial a_{pq}} \ln S\left( e^f | F \right) = \frac{S\left( \xi_p \xi_q e^f | F \right)}{S\left( e^f | F \right)}.$$ 

Suppose first that neither of the indices $p$ or $q$ is free. Then the value of $\xi_p \xi_q$ is constant for all $x \in F$ and hence

$$\frac{S\left( \xi_p \xi_q e^f | F \right)}{S\left( e^f | F \right)} = \xi_p \xi_q,$$
from which the proof follows.

Suppose now that only one of the indices $p$ and $q$, say $q$, is free. Let $F^+ \subset F$ and $F^- \subset F$ be the faces obtained by setting the $q$-th coordinate $\xi_q = 1$ and $\xi_q = -1$ respectively. Applying (2.1.1), we get

$$\frac{S\left( \xi_p \xi_q e^f | F \right)}{S\left( e^f | F \right)} = \xi_p \left( \frac{S\left( e^f | F^+ \right)}{S\left( e^f | F \right)} - \frac{S\left( e^f | F^- \right)}{S\left( e^f | F \right)} \right).$$

We apply Lemma 2.2 with

$$w_+ = S\left( e^f | F^+ \right) \quad \text{and} \quad w_- = S\left( e^f | F^- \right).$$

By (2.1.1), we have

$$w = w_+ + w_- = S\left( e^f | F \right).$$
and the angle between \( w_+ \neq 0 \) and \( w_- \neq 0 \) does not exceed \( \theta \) by the assumption of the lemma. Applying Part 1 of Lemma 2.2, we get
\[
\left| \frac{\partial}{\partial a_{pq}} \ln S(e^f|F) \right| = \left| \frac{w_+ - w_-}{w} \right| \leq \frac{|w_+| + |w_-|}{|w|} \leq \frac{1}{\cos(\theta/2)}.
\]
Applying Part 2 of Lemma 2.2, we conclude that
\[
\left| \Im \frac{\partial}{\partial a_{pq}} \ln S(e^f|F) \right| = \left| \Im \frac{w_+ - w_-}{w} \right| \leq \tan \frac{\theta}{2},
\]
which completes the proof. \( \Box \)

(2.4) Corollary. Let \( F \subset \{-1, 1\}^n \) be a face as in Lemma 2.3 and let \( f \in U(b; \delta) \) be a polynomial. Suppose that \( p \) is a fixed index of \( F \) and let \( g \in U(b; \delta) \) be a polynomial obtained by replacing the coefficient \( a_{pq} \) in \( f \) for some \( q \) by \( -a_{pq} \). Then the angle between \( S(e^f|F) \neq 0 \) and \( S(e^g|F) \neq 0 \) does not exceed
\[
\left( 2 \tan \frac{\theta}{2} \right) |\Re a_{pq}| + \frac{2|\Im a_{pq}|}{\cos(\theta/2)}.
\]
Proof. For \(-1 \leq t \leq 1\), let \( f_t : \{-1, 1\}^n \to \mathbb{R} \) be the polynomial obtained by replacing \( a_{pq} \) with \( ta_{pq} \) in \( f \), so \( f_1 = f \) and \( f_{-1} = g \) and \( f_t \in U(b; \delta) \) for \(-1 \leq t \leq 1\). Then
\[
\ln S(e^f|F) - \ln S(e^g|F) = \int_{-1}^{1} \frac{d}{dt} \ln S(e^{f_t}|F) \, dt = a_{pq} \int_{-1}^{1} \frac{\partial}{\partial a_{pq}} \ln S(e^{f_t}|F) \, dt.
\]
Consequently,
\[
|\Im \ln S(e^f|F) - \Im \ln S(e^g|F)| \leq |\Re a_{pq}| \int_{-1}^{1} \left| \Im \frac{\partial}{\partial a_{pq}} \ln S(e^{f_t}|F) \right| \, dt
\]
\[
+ |\Im a_{pq}| \int_{-1}^{1} \left| \frac{\partial}{\partial a_{pq}} \ln S(e^{f_t}|F) \right| \, dt.
\]
Applying Lemma 2.3, we complete the proof. \( \Box \)

(2.5) Proof of Theorem 1.1. First, we show that there is \( 0 < \theta < \pi/2 \) such that
\[
(2.5.1) \quad 2(1-\delta) \tan \frac{\theta}{2} + \frac{\delta^2}{5 \cos(\theta/2)} + \frac{\delta^2}{5} \leq \theta.
\]
Indeed, we can just choose \( \theta = \delta/2 \). Using that
\[
\tan x \leq x \left(1 + \frac{x}{10}\right) \quad \text{for} \quad 0 \leq x \leq \frac{1}{4}
\]
and that
\[ \cos x \geq \cos \left( \frac{1}{4} \right) \geq \frac{9}{10} \quad \text{for} \quad 0 \leq x \leq \frac{1}{4}, \]
we obtain
\[ 2(1 - \delta) \tan \frac{\theta}{2} + \frac{\delta^2}{5} \tan \left( \frac{\delta}{4} \right) + \frac{\delta^2}{5} = 2(1 - \delta) \tan \frac{\delta}{4} + \frac{\delta^2}{5} \tan \left( \frac{\delta}{4} \right) + \frac{\delta^2}{5} \]
\[ \leq 2(1 - \delta) \frac{\delta}{4} \left( 1 + \frac{\delta}{40} \right) + \frac{19 \delta^2}{45} = \frac{\delta}{2} \left( 1 - \frac{39 \delta}{40} - \frac{\delta^2}{40} \right) + \frac{19 \delta^2}{45} \leq \frac{\delta}{2} = \theta. \]
We prove by induction for \( k = 0, \ldots, n \) the following statement.

Let \( F \subset \{-1, 1\}^n \) be a face of dimension \( k \). Then \( S(e^f|F) \neq 0 \). Moreover, if \( k > 0 \) and \( q \) is a free index of \( F \) then the following holds. Let \( F^+ \subset F \) and \( F^- \subset F \) be the faces of \( F \) obtained by fixing the \( q \)-th variable \( \xi_q = 1 \) and \( \xi_q = -1 \) respectively. Then the angle between \( S(e^f|F^+) \neq 0 \) and \( S(e^f|F^-) \neq 0 \) does not exceed \( \theta \).

The statement clearly holds for \( k = 0 \). Suppose that \( k > 1 \), let \( q \) be a free index of \( F \) and let \( F^+, F^- \subset F \) be the corresponding faces, so \( \dim F^+ = \dim F^- = k - 1 \). By the induction hypothesis, we have \( S(e^f|F^+) \neq 0 \) and \( S(e^f|F^-) \neq 0 \). Moreover, \( S(e^f|F^-) = S(e^g|F^+) \), where \( g \) is obtained from

\[ f(\xi_1, \ldots, \xi_n) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^{n} b_i \xi_i \]

by replacing the coefficients \( a_{pq} \) for \( p \neq q \) by \( -a_{pq} \) and the coefficient \( b_q \) by \( -b_q \). Since \( q \) is a fixed index for \( F^+ \), replacing \( b_q \) by \( -b_q \) leads to multiplying \( S(e^f|F^+) \) by \( e^{-2b_q \xi_q} \), which results in the rotation of \( S(e^f|F^+) \) by an angle of \( 2(\Im b_q) \leq \delta^2/5 \) and some scaling. By Corollary 2.4, replacing all \( a_{pq} \) with \( -a_{pq} \) leads to a rotation of \( S(e^f|F^+) \) by at most an angle of

\[ \left( 2 \tan \frac{\theta}{2} \right) \sum_{p: p \neq q} \left| \Re a_{pq} \right| + \frac{2}{\cos(\theta/2)} \sum_{p: p \neq q} \left| \Im a_{pq} \right| \leq 2(1 - \delta) \tan \frac{\theta}{2} + \frac{\delta^2}{5} \cos(\theta/2) \]

and also some scaling. Hence the angle between \( S(e^f|F^+) \neq 0 \) and \( S(e^f|F^-) = S(e^g|F^+) \neq 0 \) does not exceed

\[ 2(1 - \delta) \tan \frac{\theta}{2} + \frac{\delta^2}{5} \cos(\theta/2) + \frac{\delta^2}{5} \leq \theta \]

by (2.5.1). Since

\[ S(e^f|F) = S(e^f|F^+) + S(e^f|F^-) \]
applying Part 1 of Lemma 2.2 with
\[ w_+ = S(e^j|F^+) \quad \text{and} \quad w_- = S(e^j|F^-), \]
we conclude that
\[ S(e^j|F) \neq 0. \]
This concludes the proof of the induction step and hence of Theorem 1.1. □

3. Proof of Theorem 1.6

First, we obtain a version of Lemma 2.2.

(3.1) Lemma. Let \( v^{++}, v^{+-}, v^{-+}, v^{--} \in \mathbb{C} \) be non-zero numbers, such that the angles

- between \( v^{++} \) and \( v^{+-} \),
- between \( v^{++} \) and \( v^{-+} \),
- between \( v^{-} \) and \( v^{+-} \),
- between \( v^{-} \) and \( v^{-+} \)
do not exceed some \( 0 \leq \theta < \pi/2 \) and let \( v = v^{++} + v^{+-} + v^{-+} + v^{-} \).

1. We have \( v \neq 0 \) and, moreover,
\[
\frac{|v^{++}| + |v^{+-}| + |v^{-+}| + |v^{-}|}{|v|} \leq \frac{1}{\cos \theta}.
\]
2. We have
\[
\left| \Im \frac{v^{++} - v^{+-} - v^{-+} + v^{-}}{v} \right| \leq \tan \frac{\theta}{2}.
\]

Proof. Clearly, the angle between any two vectors of \( v^{++}, v^{+-}, v^{-+}, v^{-} \) does not exceed \( 2\theta < \pi \). Let \( K \subset \mathbb{R}^2 = \mathbb{C} \) be the angle (cone) spanned by the four vectors. Hence the angular measure of \( K \) is at most \( 2\theta \).

The proof of Part 1 goes exactly as in the proof of Lemma 2.2.

We let \( u^{++}, u^{+-}, u^{-+}, u^{-} \) and \( u \) be the orthogonal projections of the vectors \( v^{++}, v^{+-}, v^{-+}, v^{-} \) and \( v \) respectively onto the bisector of \( K \). Then
\[
|v| \geq |u| = |u^{++}| + |u^{+-}| + |u^{-+}| + |u^{-}| \geq \cos(\theta) \left( |v^{++}| + |v^{+-}| + |v^{-+}| + |v^{-}| \right)
\]
and the proof of Part 1 follows.

The proof of Part 2 is obtained by the application of Part 2 of Lemma 2.2. Namely, let
\[
w_+ = v^{++} + v^{-} \quad \text{and} \quad w_- = v^{+-} + v^{-+},
\]
so that
\[
\frac{v_{++} - v_{+-} - v_{-+} + v_{--}}{v} = \frac{w_{+} - w_{-}}{w_{+} + w_{-}}.
\]

We claim that the angle between \(w_{+}\) and \(w_{-}\) does not exceed \(\theta\). Indeed, without loss of generality, we assume that one side of the angle \(K\) is spanned by \(v_{++}\). If the other side of \(K\) is spanned by one of the vectors \(v_{+-}\) or \(v_{-+}\) or the angle is just the ray spanned by \(v_{++}\), then the angular measure of \(K\) does not exceed \(\theta\) and hence the angle between \(w_{+}\) and \(w_{-}\) also does not exceed \(\theta\). Suppose now that the other side of \(K\) is spanned by \(v_{--}\). Without loss of generality, we assume that listed in the clockwise order, the vectors in \(K\) are \(v_{++}, v_{+-}, v_{-+}, v_{--}\). We consider the following two angles: angle \(K_1\) spanned by \(v_{++}\) and \(v_{-+}\) and angle \(K_2\) spanned by \(v_{+-}\) and \(v_{--}\). We note that the angular measure of \(K_1\) does not exceed \(\theta\) and the angular measure of \(K_2\) does not exceed \(\theta\). Vector \(w_{-}\) lies in the angle spanned by \(v_{+-}\) and \(v_{--}\) and hence in \(K_1 \cap K_2\). On the other hand, since \(K = K_1 \cup K_2\), vector \(w_{+}\) lies in at least one of the angles \(K_1\) or \(K_2\). In either case, the angle between \(w_{+}\) and \(w_{-}\) does not exceed \(\theta\). Applying Part 2 of Lemma 2.2, we conclude that
\[
\left| \Im \frac{v_{++} - v_{+-} - v_{-+} + v_{--}}{v} \right| = \left| \Im \frac{w_{+} - w_{-}}{w_{+} + w_{-}} \right| \leq \tan \frac{\theta}{2},
\]
as claimed. \(\square\)

Similar to Section 2, we introduce a set \(U(b; \delta) \subset \mathbb{C}^{(\frac{n}{3})+\binom{n}{2}}\) of cubic polynomials
\[
f(x) = \sum_{1 \leq i < j < k \leq n} c_{ijk} \xi_i \xi_j \xi_k + \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^{n} b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n)
\]
such that
\[
\sum_{j,k: j,k \neq i} |\Re c_{ijk}| + \sum_{j: j \neq i} |\Re a_{ij}| \leq 1 - \delta,
\]
\[
\sum_{j,k: j,k \neq i} |\Im c_{ijk}| + \sum_{j: j \neq i} |\Im a_{ij}| \leq \frac{\delta^2}{10} \quad \text{and}
\]
\[
|\Im b_i| \leq \frac{\delta^2}{10} \quad \text{for} \quad i = 1, \ldots, n.
\]

Next, we need a refinement of Lemma 2.3.

(3.2) Lemma. Let \(F \subseteq \{-1,1\}^n\) be a face of \(\{-1,1\}^n\). Suppose that for all \(f \in U(b; \delta)\), we have \(S(e^f|F) \neq 0\) and, moreover, the following condition is satisfied: if \(G \subseteq F\) is a face, if \(i\) is a free index of \(G\) and \(G^+ \subset G\) and \(G^- \subset G\) are the faces obtained by setting the \(i\)-th coordinate \(\xi_i = 1\) and \(\xi_i = -1\) respectively, then
the angle between numbers \( S(e^f | G^+) \neq 0 \) and \( S(e^f | G^-) \neq 0 \) does not exceed \( \theta \) for some \( 0 \leq \theta < \pi/2 \). We pick a branch of \( \ln S(e^f | F) \) for \( f \in U(b; \delta) \).

(1) Let us fix three indices \( 1 \leq p < q < r \leq n \), at most two of which are free for \( F \). Then

\[
\left| \frac{\partial}{\partial c_{pqr}} \ln S(e^f | F) \right| \leq \frac{1}{\cos \theta} \quad \text{and} \quad \left| \Im \frac{\partial}{\partial c_{pqr}} \ln S(e^f | F) \right| \leq \tan \frac{\theta}{2}.
\]

(2) Let us fix two indices \( 1 \leq p < q \leq n \), at most one of which is free for \( F \). Then

\[
\left| \frac{\partial}{\partial a_{pq}} \ln S(e^f | F) \right| \leq \frac{1}{\cos(\theta/2)} \leq \frac{1}{\cos \theta} \quad \text{and} \quad \left| \Im \frac{\partial}{\partial a_{pq}} \ln S(e^f | F) \right| \leq \tan \frac{\theta}{2}.
\]

**Proof.** If there is at most one free index, the proof follows that of Lemma 2.3. Suppose that exactly two indices, say \( p \) and \( q \) are free, while \( r \) is fixed. Then

\[
\frac{\partial}{\partial c_{pqr}} \ln S(e^f | F) = \frac{S(\xi_p \xi_q \xi_r e^f | F)}{S(e^f | F)} = \frac{\xi_r S(\xi_p \xi_q e^f | F)}{S(e^f | F)}.
\]

Let us define four faces \( F^{++}, F^{+-}, F^{-+}, F^{--} \subset F \) as follows:

- \( F^{++} \subset F \) is obtained from \( F \) by setting \( \xi_p = 1, \xi_q = 1 \);
- \( F^{+-} \subset F \) is obtained from \( F \) by setting \( \xi_p = 1, \xi_q = -1 \);
- \( F^{-+} \subset F \) is obtained from \( F \) by setting \( \xi_p = -1, \xi_q = 1 \);
- \( F^{--} \subset F \) is obtained from \( F \) by setting \( \xi_p = -1, \xi_q = -1 \).

We let

\[
\begin{align*}
v_{++} &= S(e^f | F^{++}), \\
v_{+-} &= S(e^f | F^{+-}), \\
v_{-+} &= S(e^f | F^{-+}), \\
v_{--} &= S(e^f | F^{--})
\end{align*}
\]

and observe that

\[
\frac{\partial}{\partial c_{pqr}} \ln S(e^f | F) = \xi_r \frac{v_{++} - v_{+-} - v_{-+} + v_{--}}{v_{++} + v_{+-} + v_{-+} + v_{--}}.
\]

The proof now follows by Lemma 3.1.

As in Section 2, we obtain a corollary.
(3.3) Corollary. Let \( F \subset \{-1, 1\}^n \) be a face as in Lemma 3.2 and let \( f \in \mathcal{U}(b; \delta) \) be a polynomial.

1. Suppose that \( r \) is a fixed index of \( F \) and let \( g \in \mathcal{U}(b; \delta) \) be a polynomial obtained from \( f \) by replacing the coefficient \( c_{pqr} \) in \( f \) for some \( p \) and \( q \) by \(-c_{pqr}\). Then the angle between \( S(e^f|F) \neq 0 \) and \( S(e^g|F) \neq 0 \) does not exceed

\[
\left( 2 \tan \frac{\theta}{2} \right) |\Re c_{pqr}| + \frac{2 |\Im c_{pqr}|}{\cos \theta}.
\]

2. Suppose that \( p \) is a fixed index of \( F \) and let \( g \in \mathcal{U}(b; \delta) \) be a polynomial obtained from \( f \) by replacing the coefficient \( a_{pq} \) in \( f \) for some \( q \) by \(-a_{pq}\). Then the angle between \( S(e^f|F) \neq 0 \) and \( S(e^g|F) \neq 0 \) does not exceed

\[
\left( 2 \tan \frac{\theta}{2} \right) |\Re a_{pq}| + \frac{2 |\Im a_{pq}|}{\cos \theta}.
\]

Proof. The proof is similar to that of Corollary 2.4, only that we use Lemma 3.2 instead of Lemma 2.3.

(3.4) Proof of Theorem 1.6. First, we show that there is \( 0 \leq \theta < \pi/4 \) such that

\[
2(1 - \delta) \tan \frac{\theta}{2} + \frac{\delta^2}{5 \cos \theta} + \frac{\delta^2}{5} \leq \theta.
\]

As in Section 2.5, we can choose \( \theta = \delta/2 \) (note that we assumed that \( \delta < 1/2 \) and hence we can use the estimates of Section 2.5 verbatim).

We prove by induction the same statement as in Section 2.5. The only difference is that if \( r \) is a free index of \( F \) and \( F^+, F^- \subset F \) are the faces obtained by setting \( \xi_r = 1 \) and \( \xi_r = -1 \) respectively, then \( S(e^f|F^+) = S(e^g|F^-) \), where \( g \) is obtained from \( f \) by changing all coefficients \( c_{pqr} \) to \(-c_{pqr}\), all coefficients \( a_{qr} \) to \(-a_{qr}\) and the coefficient \( b_r \) to \(-b_r\). We then use Corollary 3.3 instead of Corollary 2.4.

(3.5) Polynomials of higher degree. We don’t know if the straightforward extensions of Theorems 1.1 and 1.6 hold for polynomials \( f : \{-1, 1\}^n \to \mathbb{C} \) of degree 4 and higher (for some non-optimal estimates in that case, see [Ba17]). The reason our argument does not extend to the case of \( \deg f \geq 4 \) is that we are lacking the appropriate version of Part 2 of Lemma 3.1. In the case of \( \deg f = 4 \), that version would have looked as follows: given eight non-zero complex numbers

\[
v_{+++}, v_{++-}, v_{+-+}, v_{-++}, v_{-+-}, v_{--+}, v_{---},
\]

such that the angle between any two of them whose indices differ in one position does not exceed some small number \( \theta > 0 \), we have

\[
\left| \frac{3 v_{+++} - v_{++-} - v_{+-+} - v_{-++} + v_{+-+} + v_{-+-} + v_{--+} - v_{---}}{v_{+++} + v_{++-} + v_{+-+} + v_{-++} + v_{+-+} + v_{-+-} + v_{--+} + v_{---}} \right| \leq \tan \frac{\theta}{2}.
\]
However, the above inequality cannot hold. One can easily construct a counterexample by choosing $|v_{++}| = |v_{--}| = 1$, the angle between $v_{++}$ and $v_{--}$ equal $3\theta$, while choosing all other vectors to have a very small length. In that case, the left hand side should be about $\tan(3\theta/2)$ and our proof cannot proceed. This failure of the approach does not, of course, exclude a possibility that the extensions of Theorems 1.1 and 1.6 still hold for higher degree polynomials.

4. Approximation

Let

$$f(x) = \sum_{1 \leq i < j \leq n} a_{ij} \xi_i \xi_j + \sum_{i=1}^{n} b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n).$$

We suppose that the coefficients $a_{ij}$ and $b_i$ are real and satisfy

$$\sum_{j: j \neq i} |a_{ij}| \leq 1 - \delta \quad \text{for} \quad i = 1, \ldots, n$$

and some $0 < \delta < 1$, fixed in advance (there are no restrictions on $b_i$). Here we sketch an algorithm for approximating

$$S(f) = \sum_{x \in \{-1, 1\}^n} e^{f(x)}$$

by the method of polynomial interpolation. Without loss of generality, we assume that $\delta \leq 0.1$ and that $n$ is large enough,

$$n \geq \frac{100}{\delta^2},$$

since for smaller $n$ the sum can be computed by brute force.

(4.1) Writing $S(f)$ as $p(1)$ for a univariate polynomial $p(z)$. First, we rewrite $S(f)$ as a polynomial in some new variables. We have

$$e^{f(x)} = \left( \prod_{1 \leq i < j \leq n} e^{a_{ij} \xi_i \xi_j} \right) \left( \prod_{i=1}^{n} e^{b_i \xi_i} \right)$$

$$= \exp \left\{ - \sum_{1 \leq i < j \leq n} a_{ij} \right\} \left( \prod_{1 \leq i < j \leq n} e^{a_{ij}(\xi_i \xi_j + 1)} \right) \left( \prod_{i=1}^{n} e^{b_i \xi_i} \right).$$

Let

$$c_{ij} = e^{a_{ij}/n^2} - 1 \quad \text{for} \quad 1 \leq i < j \leq n.$$
For given \( b_1, \ldots, b_n \), we consider a polynomial

\[
P_b(c_{ij}) = \sum_{\xi_1, \ldots, \xi_n = \pm 1} \left( \prod_{1 \leq i < j \leq n} (c_{ij} + 1)^{n^2(\xi_i \xi_j + 1)} \right) \left( \prod_{i=1}^{n} e^{b_i \xi_i} \right)
\]

of degree \( n^3(n-1) \) in the \( \binom{n}{2} \) variables \( c_{ij} \). Thus we have

\[
S(f) = \exp \left\{ - \sum_{1 \leq i < j \leq n} a_{ij} \right\} P_b(c_{ij})
\]

and we want to approximate \( P_b(c_{ij}) \).

Next, for given \( c_{ij} \) and \( b_i \), we consider a univariate polynomial

\[
p(z) = P_b(zc_{ij}) = \sum_{\xi_1, \ldots, \xi_n = \pm 1} \left( \prod_{1 \leq i < j \leq n} (zc_{ij} + 1)^{n^2(\xi_i \xi_j + 1)} \right) \left( \prod_{i=1}^{n} e^{b_i \xi_i} \right)
\]

of a complex variable \( z \). Our goal is to approximate \( p(1) \).

**4.2) Showing that** \( p(z) \neq 0 \) **in a neighborhood of** \( [0, 1] \subset \mathbb{C} \). **Our next goal is to show that**

\[
p(z) \neq 0 \text{ provided } |\Re z| \leq 1 + \delta^2 \text{ and } |\Im z| \leq \frac{\delta^2}{80}.
\]

Since \( |a_{ij}| \leq 1 \) and \( n \geq 10 \), from (4.1.1) we deduce that

\[
|c_{ij} - \frac{a_{ij}}{n^2}| \leq \frac{1}{n^4} \text{ for all } i, j.
\]

In particular,

\[
|c_{ij}| \leq \frac{2}{n^2} \text{ for all } i, j.
\]

From (4.1.1), we obtain

\[
a_{ij} = n^2 \ln(1 + c_{ij}) \text{ for all } i, j.
\]

Let us choose an arbitrary \( z \in \mathbb{C} \) such that \( |z| \leq 1 + \delta^2 \) and let us define

\[
\tilde{a}_{ij} = \tilde{a}_{ij}(z) = n^2 \ln(1 + zc_{ij}) \text{ for all } i, j,
\]

\[
\tilde{a}_{ij} = \tilde{a}_{ij}(z) = n^2 \ln(1 + zc_{ij}) \text{ for all } i, j,
\]
where we choose the principal branch of the logarithm, so that \( \hat{a}_{ij}(0) = 0 \). Let

\[
\hat{f}(x) = \sum_{1 \leq i < j \leq n} \hat{a}_{ij} \xi_i \xi_j + \sum_{i=1}^{n} b_i \xi_i \quad \text{for} \quad x = (\xi_1, \ldots, \xi_n).
\]

From Section 4.1, we have

\[
(4.2.5) \quad p(z) = \exp \left\{ \sum_{1 \leq i < j \leq n} \hat{a}_{ij} \right\} S(\hat{f}).
\]

Combining (4.2.2)–(4.2.4), we obtain

\[
\hat{a}_{ij} = za_{ij} + \eta_{ij} \quad \text{where} \quad |\eta_{ij}| \leq \frac{3}{n^2} \quad \text{for all} \quad i, j.
\]

Consequently,

\[
\sum_{j: j \neq i} |\Re \hat{a}_{ij}| \leq (1 - \delta)(1 + \delta^2) + \frac{3}{n} \leq 1 - \frac{\delta}{2}.
\]

In addition, if \( |\Im z| \leq \delta^2 /80 \), then

\[
\sum_{j: j \neq i} |\Im \hat{a}_{ij}| \leq \frac{\delta^2}{80} + \frac{3}{n} \leq \frac{\delta^2}{40}.
\]

Hence by Theorem 1.1 we have that \( S(\hat{f}) \neq 0 \) and therefore by (4.2.5) we conclude that (4.2.1) holds.

**4.3 Computing \( p^{(k)}(0) \).** As discussed in Section 2.2 of [Ba16], see also [PR17] and [Ba19] for some enhancements, as soon as \( p(z) \neq 0 \) in some neighborhood \( U \) of the interval \( [0, 1] \subset \mathbb{C} \), to approximate \( p(1) \) within relative error \( 0 < \epsilon < 1 \), it suffices to compute the derivatives \( p^{(k)}(0) \) for \( k = \gamma (\ln \deg p - \ln \epsilon) \) where \( \gamma = \gamma(U) > 0 \). Since in our case \( \deg p \leq n^4 \), to approximate \( S(f) = p(1) \) within relative error \( 0 < \epsilon < 1 \), it suffices to compute \( p^{(k)}(0) \) for \( k = O(\ln n - \ln \epsilon) \), where the implied constant in the “O” notation depends on \( \delta \) alone.

From (4.1.2), we obtain

\[
p^{(k)}(0) = 2^k n^{2k} \sum_{\xi_1, \ldots, \xi_n = \pm 1} \left( \prod_{i=1}^{n} e^{b_i \xi_i} \right) \sum_{\xi_{i_1} \xi_{j_1} = \ldots = \xi_{i_k} \xi_{j_k} = 1} c_{i_1 j_1} \cdots c_{i_k j_k},
\]

where the inner sum is taken over all ordered \( k \)-sets of pairs \( i_1 < j_1, i_2 < j_2, \ldots, i_k < j_k \), such that the products \( \xi_{i_1} \xi_{j_1}, \ldots, \xi_{i_k} \xi_{j_k} \) are all equal 1.
It is convenient to rewrite the above sum in the graph notation. Let $K_n$ be the complete undirected graph with set $V = \{1, \ldots, n\}$ of vertices and set $E$ of edges. We assign weight $c_{ij}$ to edge $\{i, j\}$. We call a map $\sigma : V \to \{-1, 1\}$ consistent on an edge $u = \{i, j\}$ if $\sigma(i) = \sigma(j)$. Then

$$
p(k)(0) = 2^k n^{2k} \sum_{\sigma : V \to \{-1, 1\}} \left( \prod_{i=1}^{n} e^{b_i \sigma(i)} \right) \sum_{u_1, \ldots, u_k \in E : \sigma \text{ is consistent on each } u_1, \ldots, u_k} c_{u_1} \cdots c_{u_k} \sum_{\sigma : V \to \{-1, 1\}} \left( \prod_{i=1}^{n} e^{b_i \sigma(i)} \right).
$$

For a given $k$, there are not more than $n^{2k}$ ordered sets of $k$ distinct edges $u_1, \ldots, u_k$. Given such an ordered set $u_1, \ldots, u_k$, let $W \subset V$ be the set of vertices of $u_1, \ldots, u_k$. Then $|W| \leq 2k$ and there are at most $2^k$ maps $\sigma_0 : W \to \{-1, 1\}$ that are consistent on each edge $u_1, \ldots, u_k$. Finally, given such a map $\sigma_0$, we have

$$
\sum_{\sigma : V \to \{-1, 1\}} \left( \prod_{i=1}^{n} e^{b_i \sigma(i)} \right) = \prod_{i \in W} e^{b_i \sigma_0(i)} \prod_{i \in V \setminus W} (e^{b_i} + e^{-b_i}).
$$

Summarizing,

$$
p(k)(0) = 2^k n^{2k} \sum_{u_1, \ldots, u_k} c_{u_1} \cdots c_{u_k} \sum_{\sigma_0 : W \to \{-1, 1\}} \left( \prod_{i \in W} e^{b_i \sigma_0(i)} \prod_{i \in V \setminus W} (e^{b_i} + e^{-b_i}) \right),
$$

where the outer sum is taken over at most $n^{2k}$ ordered sets of $k$ edges and the inner sum is taken over at most $2^k$ consistent maps $\sigma_0$ on the set $W$ of vertices of $\{u_1, \ldots, u_k\}$. Hence the complexity of computing $p^{(k)}(0)$ is $n^{O(k)}$ and since $k = O(\ln n - \ln \epsilon)$, we obtain an algorithm of quasi-polynomial $n^{O(\ln n - \ln \epsilon)}$ complexity to approximate $S(f)$.

The extension of the algorithm to cubic polynomials $f$ is straightforward. We use then Theorem 1.6 instead of Theorem 1.1 to ascertain that the auxiliary univariate polynomial $p(z)$ does not have roots in a neighborhood of $[0, 1] \subset \mathbb{C}$.
